Revised Manuscript Received April 21, 1998

We wish to describe the first example of a transition metal methyl/hydride complex in which the hydrogen atoms of the alkyl and hydride are exchanging at a rate sufficient to be dynamic on the NMR time scale. The results suggest that an alkane complex \(\text{L}_x\text{M(CH}_4\text{)}\) is formed reversibly from the methyl/hydride complex over 100 times per s at \(-100\) °C.

Protonation of the osmium(II) alkyl \((\text{C}_5\text{Me}_5)\text{Os}((\text{dmpm})(\text{CH}_3))\), where dmpm is bis(dimethylphosphino)methane, with \(-1\) equiv of the carbon acid \(\text{H}_2\text{C}(\text{SO}_2\text{CF}_3)_2\) in \(\text{CDFCl}_2\) at \(-120\) °C yields the osmium(IV) methyl/hydride complex \((\text{C}_5\text{Me}_5)\text{Os}((\text{dmpm})(\text{CH}_3)\text{H})\)

The \(^1\text{H}\) NMR spectrum of \(\mathbf{1}\) at this temperature features a resonance at \(-13.03\) for the Os–H group and a resonance at \(0.54\) for the Os–Me group; a HMBC experiment showed that the latter peak is correlated with the Os–Me resonance at \(-37.9\) in the \(^{13}\text{C}\) [\(^{1}\text{H}\)] NMR spectrum. The \(^{13}\text{P}\) [\(^{1}\text{H}\)] NMR spectrum of \(\mathbf{1}\) shows that the two ends of the dmpm ligand are inequivalent, as expected for a structure in which the methyl and hydride resonances are mutually “cisoid.” There is no evidence of the formation of the “transoid” isomer under any conditions.

Remarkably, when the temperature is raised, the Os–H and Os–Me peaks broaden due to onset of coalescence (Figure 1); this process also exchanges the two ends of the dmpm ligand. Simulations of the line shapes are consistent with an exchange process that permutes the four hydrogen atoms in the Os–H and Os–Me sites. The exchange rates deduced from the simulations are 10, 22, 45, 85, and 170 s\(^{-1}\) at \(-120, -115, -110, -105, \) and \(-100\) °C, respectively.

Definitive evidence that the hydrogen atoms in the Os–H and Os–Me sites are exchanging with one another has been obtained from spin saturation transfer experiments. Presaturation of the Os–H resonance leads to selective loss of intensity of the Os–Me resonance as a function of the presaturation time.

(2) This osmium(II) alkyl can be prepared from \((\text{C}_5\text{Me}_5)\text{Os}(\text{dmpm})\)Br, which has been recently described. See: Gross, C. L.; Girolami, G. S. Organometallics 1996, 15, 5359–5367.

(4) NMR data for \(\mathbf{1}\) in CDFCl; \(-120\) °C. \(^1\text{H}\) NMR: \(\delta 4.79\) (4-line pattern, \(\Sigma = 37.8\) Hz, PCH); \(4.06\) (s, \((\text{SO}_2\text{CF}_3)_2\)CH); \(3.56\) (4-line pattern, \(\Sigma = 40.3\) Hz, PCH)); \(1.94\) (s, \(\text{CH}_3\)); \(1.89\) (br s, \(\text{PMe}_2\)); \(1.78\) (m, \(2\text{PMe}_2\)); \(1.35\) (“d”, \(J_{\text{PC}} = 8.7\) Hz, \(\text{PMe}_2\)); \(0.55\) (“d”, \(J_{\text{PC}} = 7.2\) Hz, Os–Me); \(-13.03\) (dd, \(J_{\text{PP}} = 18.2, 39.6\) Hz, Os–H); \(^{13}\text{C}\) [\(^{1}\text{H}\)] NMR: \(\delta 120.6\) (q, \(J_{\text{CP}} = 322.7\) Hz, \((\text{SO}_2\text{CF}_3)_2\)CH); \(96.1\) (s, \(\text{CMe}_5\)); \(52.4\) (s, \((\text{SO}_2\text{CF}_3)_2\)CH); \(51.0\) (t, \(J_{\text{PC}} = 32.0\) Hz, PCH)); \(26.6\) (“d”, \(J_{\text{PC}} = 44.4\) Hz, PMe); \(16.4\) (“d”, \(J_{\text{PC}} = 31.1\) Hz, \(2\text{PMe}_2\)); \(10.0\) (s, \(\text{CH}_3\)); \(9.0\) (m, \(\text{PMe}_2\)); \(-37.9\) (m, Os–Me); \(^{31}\text{P}\) [\(^{1}\text{H}\)] NMR: \(\delta -69.6\) (d, \(J_{\text{PP}} = 114.1\) Hz), \(-77.0\) (d, \(J_{\text{PP}} = 114.1\) Hz).

(6) The rates given are for hydrogen atoms leaving the methyl site.

Figure 1. Temperature dependence of the methyl (left) and hydride (right) resonances seen in the 500 MHz [\(^1\text{H}\)] NMR spectrum of \(\mathbf{1}\). Simulations of these line shapes are given in the Supporting Information.

Figure 2. Spin saturation transfer results showing decay of the methyl resonance upon irradiating the hydride resonance in \(\mathbf{1}\) at \(-110\) and \(-105\) °C for different lengths of time. The Os–Me peak intensity is plotted as a function of presaturation time, which increases from 0 to 200 ms (left to right) in increments of 2 ms.

(Figure 2). We find that \(k\) equals 9.4, 20, 42, 81, and 160 s\(^{-1}\) at temperatures of \(-120, -115, -110, -105, \) and \(-100\) °C, respectively. These rate constants agree very closely with those deduced above from the simulations of the line shapes. From these values, we calculate that \(\Delta H = 7.1 \pm 0.9\) kcal/mol and \(\Delta S = -6.5 \pm 5\) eu for the hydrogen scrambling process. At
Reducive elimination of methane occurs following first-order kinetics at measurable rates above $-95 \, ^\circ C$, but this process involves a different transition state because the activation energy, $\Delta G^\ddagger = 13.5 \, kJ/mol$, is higher than that for hydrogen scrambling.

Previous studies of $L$-$M$($R$) complexes suggest that, in a few cases, the deuterium label can scramble into hydrogen positions on the alkyl ligand $R$ at temperatures near that at which the compound decomposes.\(^9\)\textendash \(^{16}\) When referenced to a common temperature, however, the methyl/hydride scrambling rate we observe for 1 is millions of times faster than the scrambling rates seen in these other complexes. The exchange process in 1 is the only one that is detectable by changes in the line widths of the $^1H$ NMR resonances or by a spin saturation transfer experiment.

Although exchange of the Os$-$CH$_3$ and Os$-$H hydrogen atoms could take place by means of $\sigma$-hydrogen elimination to form an osmium methylene dihydride intermediate (see Scheme 1), this mechanism is unlikely because a 20-electron intermediate would be generated. Processes that might reduce the electron count, such as $\pi^1 \rightarrow \pi^1$ slippage of the C$_2$Me$_5$ ring and dissociation of one arm of the phosphine ligand, have very high activation barriers.

\(^{(7)}\) For a description of spin saturation transfer experiments, see: Faller, J. W. In Determination of Organic Structure by Physical Methods; Nachod, F. C.; Zuckerman, J. J., Eds.; Academic: New York, 1973; Chapter 2. Although the diminution of the methyl resonance could be caused by a negative nuclear Overhauser enhancement, this possibility can be ruled out because negative NOEs are not expected for small molecules such as 1, and because the diminution of the Os$-$Me resonance at long saturation times becomes significantly more pronounced (not less pronounced) as the temperature is raised.

\(^{(8)}\) Errors in the activation parameters have been calculated by propagation of error formulas given in Morse, P. M.; Spencer, M. D.; Wilson. S. R.; Girolami, G. S. Organometallics 1986, 15, 1466–1655.

\(^{(13)}\) Parkin, G.; Bercaw, J. E. Organometallics 1989, 8, 1172–1179.

\(^{(16)}\) In only one other case have the activation parameters $\Delta H^\ddagger$ and $\Delta S^\ddagger$ been measured for an alkyl/hydride scrambling process in a study of [Cp$_2$Re(CH$_3$)D$_2$]+. Heinekey showed that $\Delta H^\ddagger = 22.3 \pm 1.9 \, kJ/mol$ and $\Delta S^\ddagger = 24 \pm 9 \, $ for the reaction which scrambles deuterium into the methyl hydrogen sites.\(^12\)

\(^{(17)}\) Gross, C. L.; Girolami, G. S. Unpublished observations.

\(^{(18)}\) The lower limit is set by the observation that no resonances due to the methane tautomer are observed at $-120 \, ^\circ C$, so that its equilibrium concentration must be less than $\sim 1$.
